ABSTRACT

Purpose: In this study, we prospectively investigated the relationship between bone marrow edema (BME) and odontogenic cysts and explored the possibility of using dual-energy computed tomography (DECT) as an auxiliary tool for the diagnosis of odontogenic cysts.

Methods: This cross-sectional study included 73 patients who underwent the DECT scan and surgery for odontogenic cysts or odontogenic tumors. The virtual noncalcium (VNCa) computed tomography (CT) values and CT values were measured at several sites. The predictor variable was diagnosis, and the other variables included age, sex, and sites. The primary outcome was VNCa CT value. Variables were tested using the chi-square test or Kruskal–Wallis test. The VNCa CT and CT values were tested using the Scheffe test for multiple comparisons. All variables were analyzed as independent variables affecting the VNCa CT values around the lesion in the multiple regression analysis.

Result: There were 35 men and 38 women. The mean patient age was 50.0 ± 19.5 years (range: 8–86). The VNCa CT values (-6.2 ± 34.3) around the lesion in patients with RCs were significantly higher than those in patients with dentigerous cysts (-44.4 ± 28.6) and odontogenic keratocysts (-67.3 ± 19.5). In multiple regression analysis, the VNCa CT values around the lesion showed a significant positive correlation with histological results (regression coefficient: -0.605, P < 0.001).

Conclusion: The presence of BME is associated with radicular cysts, and DECT can be used as an auxiliary tool for radicular cyst diagnosis.

Key words: prospective, dual-energy computed tomography, odontogenic cysts, bone marrow edema, head and neck

1 INTRODUCTION

The quality and clinical applications of computed tomography (CT) made remarkable progress by employing computational abilities for iterative reconstructions. Recently, dual-energy CT (DECT) became available in clinical practice. DECT uses two datasets with different energy spectra in contrast to single energy scanning methods that use only one spectrum. Therefore, DECT has several advantages such as visualization and quantification of iodine, automated bone subtraction in CT angiography, detection of perfusion defects caused by pulmonary embolism, and detection of bone marrow edema (BME)¹⁻⁵.

8 BME is not a disease but a general condition arising due to various factors including trauma and 9 hemorrhage in the bone marrow following a bone fracture and inflammation associated with conditions such 10 as osteomyelitis, osteonecrosis, arthritis of the joints, and bone marrow infiltration by tumor cells⁶⁻⁸. In the 11 field of orthopedics, BME is a marker for potential disease progression of osteonecrosis of the femoral head and is correlated with worsening pain9,10. Hence, early detection of BME is important to predict the 1213deterioration of the patient's condition and worsening of the symptoms. Magnetic resonance imaging (MRI) 14is the standard diagnostic tool for the detection of BME because the edema cannot be detected using conventional CT^{6,11}. However, MRI cannot be routinely used for all patients with cysts because it is expensive, 1516requires long examination time, and has restricted use in patients with claustrophobia and metal implant in the 17body. Moreover, the complex anatomy and close proximity of various tissues in the head and neck region 18complicate the diagnosis of BME in this region. However, recently, DECT is being used to visualize subtle 19bone involvement in osteomyelitis, osteonecrosis, and cancers in the head and neck region⁸. However, further 20research is needed to investigate whether BME in the head and neck region is reliably detected by DECT. At 21present, no study has investigated the relationship between BME and odontogenic cysts using DECT.

Odontogenic cysts are categorized into developmental and inflammatory cysts based on their origin. Although odontogenic cysts have various histological types, inflammatory cysts are usually radicular cysts (RCs) and developmental cysts are usually dentigerous cysts (DCs) or odontogenic keratocysts (OKCs)¹²⁻¹⁴. These cysts require different treatment approaches. For example, careful cystectomy is necessary in OKCs because of the high risk of recurrence, and apicoectomy of the teeth involved is necessary in RCs. These cysts sometimes have similar image features on conventional radiographs. Although biopsy is often needed before

1	surgery, repeated invasive procedures impose a burden on the patients and increase the risk of infection.
2	Clinically, there are patients who refuse biopsy for reasons of repeated surgical invasion.

The purpose of this study was to investigate the relationship between BME and odontogenic cysts and explore the possibility of using DECT as an auxiliary tool for diagnosis. We hypothesized that the presence of BME, as detected by DECT, is associated with odontogenic cysts. The specific aims of the study were to compare the virtual noncalcium (VNCa) values among each histopathological diagnosis.

1 MATERIALS & METHODS

2 Study design/sample

3 The investigators designed and conducted a cross-sectional study. This study was approved by the 4 institutional review boards of Kobe University Graduate School of Medicine and the participating hospitals $\mathbf{5}$ (authorization number: 180191). Each patient was informed about surgery-associated risks and provided 6 consent for using their CT findings. We published information regarding this study, and patients were allowed $\overline{7}$ to opt out of this study anytime. The study population comprised all patients who underwent DECT and 8 surgery for an odontogenic cyst or odontogenic tumor between September 2018 and December 2020 at the 9 Department of Oral and Maxillofacial Surgery of Kobe University Hospital. The inclusion criteria were as 10 follows: cases that were clinically identified as an odontogenic cyst or tumor by orthopantomography, and 11 cases wherein patients underwent DECT and surgery for an odontogenic cyst or odontogenic tumor. The 12exclusion criteria were as follows: cases wherein DECT or surgery was not performed, cases in which the 13diameter of the lesion is <5 mm, immeasurable cases involving severe artifacts in BME, cases with little 14cancellous bone required to measure BME, and cases with recurrent cysts or tumors.

15

16 Variables

17 The predictor variable was histological results. Histological results were classified into four groups 18 (RCs, OCs, OKCs, and others). The primary outcome variable was BME (VNCa CT values). The other 19 variables were sex, age, lesion site (anterior or molar region), and jawbone involved (maxillary or mandible).

20

21 Data collection methods

Data assessed for each patient included sex, age, histological results, and lesion site. The investigator obtained the clinical data from electronic medical records. VNCa CT values and CT values were measured. The data obtained for each subject were entered into a data sheet.

The included subjects were examined with a third generation DECT scanner (Somatom Force; Siemens Healthineers, Erlangen, Germany). The scanner was equipped with two X-ray tubes, tube A and tube B. Tube voltages were set at 100 and 150 kVp for the tubes A and B, respectively, and a tin filter was used in

1 the tube B (Sn150 kVp). The predefined tube current-time product ratio was set at 1.6:1 (tube A, 260 quality $\mathbf{2}$ reference mAs; tube B, 144 quality reference mAs). Three different images were retrieved with each DECT 3 scan: 100 kVp, Sn150 kVp, and weighted average (calculated from the tube A and B data at a ratio of 0.4:0.6) 4 to resemble the contrast properties of a 120-kVp standard CT image. Dual-energy-specific data were obtained $\mathbf{5}$ by reconstructing the axial sections of the 100 and Sn150 kVp data sets (section thickness 1.0 mm, increment 6 0.7 mm) with a bone kernel (Br64) and a soft-tissue kernel (Qr40). Postprocessing of the data from the CT $\overline{7}$ images was performed using a software (Syngo, via version VB20A; Siemens Healthineers) with a 8 three-material decomposition algorithm for bone mineral, yellow marrow, and red marrow. The relative 9 contrast ratio was set to a value of 1.53 at 100 and Sn150 kV. The strength of the smoothing filter was set to 2 10 virtual noncalcium (VNCa) and the reconstructions were created as color-coded images consolidated with 11 weighted average CT images using the BME setting in the Syngo Dual Energy software.

12BME on DECT were detected by visual evaluation of the color-coded VNCa reconstruction images. 13It was represented in purple in the normal and fatty bone marrow with a very low attenuation, and represented 14in green with increased attenuation in BME (Figure 1). BME was graded from 0-3 (0 = no BME, 1 = mildBME, 2 = moderate BME, and 3 = marked BME) for clinical purposes according to Timmer et al¹⁴. The 1516quality of the DECT was subjectively classified as 1 = excellent, 2 = good, 3 = moderate, and 4 = poor. The 17values of VNCa CT and CT (in Hounsfield units [HUs]) were obtained from color-coded VNCa images by 18using circular region of interests (ROIs) of 5 mm² (Figure 2). The values were obtained at horizontal or 19coronal planes where the lesion had the largest diameter. The VNCa CT values in center of the lesion were 20defined as "the VNCa CT values in the lesion." The VNCa CT values measured within 10 mm of the lesion 21were defined as "the VNCa CT values around the lesion." When the VNCa CT values could be measured in 22several point around the lesion, the average values were used as results. The corresponding values from the 23opposite side of the lesion were defined as "the VNCa CT values in normal bone." The CT values were 24measured similar to the VNCa CT values. All the ROIs were placed carefully to avoid strong interference 25from the root of teeth and the cortical bone.

26 Statistical analyses

27

Statistical analyses were performed using SPSS, version 22.0 (IBM Corp., Armonk, NY, USA), and

1	Ekuseru-Toukei 2012 software (Social Survey Research Information Co., Ltd., Tokyo, Japan). Continuous
2	variables were tested using the Kruskal-Wallis test, and categorical variables were tested using the chi-square
3	test. The VNCa CT values around the lesion among each histological result and the impression of BME were
4	tested using the Scheffe test following the Kruskal-Wallis test for multiple comparisons of ordinal variables.
5	All the variables were analyzed as independent variables affecting the VNCa CT values around the lesion in
6	multiple regression analysis. Variables with a variance inflation factor of greater than 10 were excluded. The
7	data were entered in a multiple regression analysis in which the patients were divided according to the
8	histological results (RCs, OCs, OKCs, and others), lesion site (anterior vs. molar region), and the jawbone
9	involved (maxillary vs. mandible). Probability values of less than 0.05 were considered as being statistically
10	significant.
11	
12	

1 RESULTS

 $\mathbf{2}$ The study group included 73 patients (35 men and 38 women). Mean patient age was 50.0 ± 19.5 3 years (range: 8-86). Data of patient variables and the characteristics and histological results of the lesions are 4 shown in Table 1. The most common histological type of the odontogenic cyst was RC with 36 (49.3%) cases. $\mathbf{5}$ There were 24 (32.9%) cases of DCs and 6 (8.2%) cases of OKCs (Table 1). The representative images of RC, 6 DC, and OKC are shown in Figure 3. The most common lesion site in patients with DCs was the molar region $\overline{7}$ of the mandible (95.8%). Moderate and marked BME in the visual impression were observed only in patients 8 with RCs (Table 1). According to the subjective quality assessment of DECT images, 28 images (38.4%) were 9 excellent, 22 (30.1%) were good, 18 (24.7%) were moderate, and 5 (6.8%) were poor (Table 1). The reasons 10 for moderate- and poor-quality images included artifacts (2 cases) and too little cancellous bone (21 cases) to 11 measure BME. In visual impression of BME, the VNCa CT values around the lesion were -50.7 ± 29.5 HUs, 12 -19.0 ± 35.1 HUs, 5.8 ± 35.0 HUs, and 11.1 ± 20.3 HUs in no, mild, moderate, and marked BME, respectively. 13The VNCa CT values of mild and marked BME were significantly higher than those of no BME (P < 0.05) 14(Figure 4a). The VNCa CT values of marked BME were significantly higher than those of moderate BME (P 15< 0.05) (Figure 4a). Data of patient variables and the VNCa or CT values are shown in Table 2. The VNCa 16CT values in the normal bone of the mandible were significantly higher than those of the maxilla (Table 2). 17The CT values around the legion of the maxilla were significantly higher than those of the mandible (Table 2). 18Data of histological results and the VNCa or CT values are shown in Table 3. The VNCa CT values and CT 19values in each histological result are shown in Figures 4b, 4c, 5a, 5b, 5c, and 5d. The VNCa CT values in the 20lesion and normal bone and the CT values in all measurement sites were not significantly associated with 21histological results (Figures 4b, 4c, 5a, 5b, 5d). However, the VNCa CT values around the lesion were 22significantly more in patients with RCs than in patients with DCs and OKCs (P < 0.05) (Table 3, Figure 5c). 23Table 4 presents the standardized regression coefficients and adjusted R-square for factors affecting 24the VNCa CT values around the lesion in the multiple regression analysis. The VNCa CT values around the

25 lesion positively correlated with the histological results. The combination of these variables explained 33.3%

26 (low) of the variance in the regression analysis of the VNCa CT values around the lesion.

27

1 **DISCUSSION**

The purpose of this study was to investigate relationship between BME and odontogenic cysts and explore the possibility of using DECT as an auxiliary tool for diagnosis. We hypothesized that the presence of BME, as detected on DECT, is associated with odontogenic cysts. The specific aims of the study were to compare the VNCa values among each histopathological diagnosis. In this study, the VNCa CT values around the lesion in patients with RCs were significantly higher than those in patients with DCs and OKCs. Moreover, moderate and marked BME in the visual impression were observed only in patients with RCs.

8 The jaw bones have a thick cortical bone and little bone marrow and cancellous bone unlike the 9 spine and the long bones. Additionally, the mandible has a mandibular canal with abundant blood flow. The 10 thick cortical bone (Figure 6) and the mandibular canal (Figure 7) increase the difficulty in obtaining the 11 VNCa CT values and CT values. In this study, the diagnosis of BME in most cases was comparatively easy, 12although 5 (6.8%) cases were difficult to diagnose. Therefore, it is possible to detect BME in the head and 13neck despite the unfavorable anatomy of the region. Existence of metal artifacts makes the diagnosis of BME 14difficult on both DECT and MRI. In particularly, metal artifacts often appear in the head and neck region 15because of dental restorations, prosthesis, and implants. Virtual monoenergetic imaging reconstructions can be used to reduce metal artifacts, although only 2 cases had severe artifacts in this study¹⁵⁻¹⁷. 16

17Since ancient times, the discrimination diagnosis of an odontogenic cyst or odontogenic tumor was 18well known using radiographic features. RCs have radiolucent circular areas and continuity with the apex of 19teeth along with infected or necrotic pulp. DCs have radiolucent circular areas with sclerotic margins around 20tooth crowns¹⁸. OKCs have aggressive and infiltrative features with frequent recurrence¹⁹. OKCs have 21unicystic or multicystic radiolucent circular areas similar to RCs or DCs¹⁹. These cysts cannot be well 22distinguished radiologically; however, a probable diagnosis can be made. For example, if RCs has a large 23diameter involving multiple teeth, then the diagnosis may be difficult. Therefore, several studies tried to 24distinguish odontogenic cysts and tumors using CT values (HUs)^{20, 21}. HU assessment of CT is widely applied as an easy diagnostic tool for various diseases²². Uchara et al. reported the mean HU values of 51.1 ± 11.8 for 25RCs, 52.8 ± 12.2 for DCs, and 37.9 ± 12.8 for OKCs²⁰. Crusoé-Rebello et al reported that the average HU 26was 28.4 ± 10.5 (-22.9–97.9) for OKCs²¹. Other reports demonstrated 3.9–22.9 HUs for DCs^{23, 24}. In this 27

study, the CT values (HUs) in the lesion were 60.2 ± 42.4 for RCs, 44.8 ± 20.8 for DCs, and 57.3 ± 63.3 for 1 $\mathbf{2}$ OKCs. The CT values of OKCs were higher than those reported in other studies^{20, 21}. OKCs have highly 3 viscous content that includes keratin²⁵. RCs also have a highly viscous content similar to that of OKCs including cell debris containing proteins and intracellular particles²⁵. On the contrary, DCs contain fluid 4 accumulation between reduced enamel epithelium and the tooth $crown^{25}$. The results may be related to the $\mathbf{5}$ content and viscosity of cystic fluid because protein concentration and viscosity highly affect the CT values²⁶, 6 ²⁷. However, careful consideration is needed before generalizing this result because of the small population $\overline{7}$ 8 size and large dispersion of cases.

9 BME is a prodrome of bone destruction and a prediction marker for worsening of symptoms^{9, 10}. It is also one of the first signs of inexplicable pain or teeth mobility²⁸. Recently, DECT has not become 10 11 available in clinical practice to detect BME caused by various diseases¹⁻⁵. It is being used to visualize subtle 12bone involvement in oncology, osteomyelitis, and osteonecrosis of the head and neck region⁸. The sensitivity 13and specificity of DECT for the detection of BME with VNCa DECT reconstructions were investigated in 14numerous studies and were found to be relatively high at 82–96% and 83–98%, respectively²⁸⁻³⁰. Therefore, 15DECT is a reliable diagnostic tool for the detection of BME. Theoretically, inflammatory cysts such as RCs 16cause inflammation and BME around the lesion. Developmental cysts such as DCs and OKCs are not 17expected to cause BME unless infected. However, there has been no study that investigated the relationship 18between BME and odontogenic cysts. Therefore, the strength of this study was to demonstrate the 19relationship between BME and odontogenic cysts. In the future, we may be able to distinguish odontogenic 20cysts with similar image features without needing biopsy. On the contrary, this study had several limitations. 21First, the present prospective study was an explorative study with a relatively small heterogeneous population. 22In particular, there were only 6 patients with OKCs. Second, BME may be associated with periapical, 23periodontal, and preoperative infections. In this study, these causative factors of inflammation were not 24investigated. Therefore, although the demographic factors did not affect BME in multiple regression analysis, 25bias could not be completely excluded.

In conclusion, the presence of BME is associated with RCs, and DECT can be used as an auxiliary
 tool for RC diagnosis. The VNCa CT values around the lesion in patients with RCs were significantly higher

1	than those in patients with DCs and OKCs. Moreover, moderate and marked BME in the visual impression
2	were observed only in patients with RCs. The VNCa CT values and detection of BME may provide additional
3	information to aid the diagnosis in ambiguous cases of odontogenic cysts. Future research using a large-scale
4	cohort and investigating predictors of BME including inflammation should be conducted.
