## Abstract

The combined effects of management history and ecosystem connectivity make it difficult to predict future dynamics of abandoned, unmanaged ecosystems. In Japan, unmanaged, secondary forests (*satoyama*) face risk of arrested or diverted succession, due to extensive human influence across the landscape. Proximity to climax forests, which function as seed sources could determine the course of succession of abandoned *satoyama*. Here, we investigated spatial/temporal variation of species composition and stand structure of abandoned *satoyama* adjacent to a mature lucidophyllous forest in warm-temperate Japan to elucidate the course of succession after abandonment. Two study plots were established in the unmanaged, secondary forest at varying distances from the mature lucidophyllous forest. We calculated vegetation similarity indices among the plots to elucidate spatial variation and temporal change of species composition and stand structure and visualized relationships using nMDS (non-metric multidimensional scaling) ordination. Over the past 15 years, species composition and stand structure of the secondary forest changed following the normal sere of succession. This was because shade-intolerant shrubs, such as *Rhododendron* were replaced by recruitment of climax species originating from the lucidophyllous forest. However, *Quercus serrata* (deciduous oak) and shade-intolerant evergreen trees continued to dominate the upper-canopy. Although the adjacent lucidophyllous forest is an effective seed source for recruitment of climax species, it may take several decades for the secondary forest to reach late-successional composition and structure, due to legacy effects of past management.

**Keywords:** traditional forest management, legacy effects, plagiosere, forest fragmentation, recruitment limitation

## 38 **Introduction**

39 Traditional agricultural landscapes are rapidly disappearing due to socio-economic changes and  
40 modernization (Agnoletti 2007; Dobrovodská et al. 2019). However, effects of past land management  
41 practices (legacy effects) can persist for decades to centuries after traditional practices are abandoned,  
42 influencing the subsequent trajectory of ecosystem dynamics, such as vegetation succession, carbon  
43 stocks, nutrient cycling, etc. (Foster et al. 2003; Hermy and Verheyen 2007). In addition, as human-  
44 domination of the landscape proceeds, natural ecosystems become more fragmented, negatively  
45 influencing landscape-scale ecosystem processes such as metapopulation dynamics and forest  
46 succession (Baiamonte et al. 2015; Duelli and Obrist 2003; Martín-Queller and Saura 2013). The  
47 combined effects of ecological history and ecosystem connectivity complicates succession and  
48 dynamics of abandoned, unmanaged ecosystems (Foster et al. 2003).

49 Satoyama are secondary forests traditionally managed under coppice forestry to obtain  
50 firewood, organic fertilizer and other forest resources in the traditional agricultural landscape of Japan  
51 (Morimoto 2011; Takeuchi et al. 2003; Yokohari and Bolthouse 2011). Recent research has shown that  
52 traditional agricultural management associated with satoyama landscapes maintains a mosaic of forests  
53 at various stages of succession (Iwachido et al. 2020; Katoh et al. 2009; Yamasaki et al. 2000).  
54 Traditionally, coppice management had prevented succession of satoyama to climax forest (Kobori  
55 and Primack 2003) and maintained open forests at early stages of succession dominated by shade-  
56 intolerant species (Nagaike et al. 2003; Takeuchi 2010). Traditional agricultural landscapes in Japan

57 are rapidly disappearing (Takeuchi 2010; Washitani 2001). Many satoyama forests in Japan were  
58 abandoned in the 1960-70s as firewood and organic fertilizer were replaced by fossil fuel and chemical  
59 fertilizer (Jiao et al. 2019). Thus these secondary forests have been unmanaged for 50-60 years and are  
60 now in mid-succession.

61 In warm-temperate Japan, the unmanaged forests are transitioning from dominance by shade-  
62 intolerant, deciduous broad-leaved trees (e.g., *Quercus variabilis*, *Quercus serrata*) to increasing  
63 abundance of shade-tolerant, evergreen broadleaved trees invading the understory and shrub layers  
64 (Hirayama et al. 2011; Ito 2007; Nakajima et al. 2018). Similar dynamics are observed in abandoned  
65 coppice-managed woodlands in Europe (Douda et al. 2017; Hedl et al. 2010; e.g., Keith et al. 2009). In  
66 warm-temperate Japan, unmanaged secondary forests are expected to succeed to lucidophyllous forest,  
67 the potential climax vegetation (Miyawaki 2004; Nakagoshi and Hong 2001; Nakajima et al. 2018).  
68 However, recruitment limitation due to lack of seed sources could arrest vegetation dynamics at mid-  
69 succession (e.g., Acácio et al. 2007). Furthermore, invasion by non-native species could divert the  
70 course of vegetation succession (plagiosere, Moriyama et al. 1984; Tojima et al. 2004). The future  
71 course of succession of unmanaged secondary forests to potential climax vegetation, therefore, is  
72 uncertain.

73 Because of extensive human influence across the landscape, climax forests are rare globally  
74 (Rackham 2008). In warm-temperate Japan, the few climax forests in populated areas are preserved in  
75 shrines and temples, for purposes of religious worship (Kamada 2005; Ishii et al. 2010). Such forests

are rare specimens of the potential climax vegetation (Miyawaki 1998), and could function as seed sources of climax species. Here, we investigated spatio-temporal variation in species composition and stand structure of an unmanaged secondary forest adjacent to a preserved lucidophyllous forest at a temple in western Japan. Observations indicated that the secondary forest, which has been unmanaged for nearly 60 years, is being invaded by shade-tolerant, evergreen species originating from the lucidophyllous forest. This has resulted in a spatial gradient of successional stages with increasing distance from the lucidophyllous forest (Azuma et al, 2014). To take advantage of this unique setting, we established research plots along this spatial gradient to investigate spatial variation in species composition and stand structure as well as temporal change over 15 years. Our objective was to elucidate the course of succession of abandoned satoyama to lucidophyllous forest in warm-temperate Japan.

87

## 88 **Study Site and Methods**

The study was conducted in an unmanaged secondary forest and adjacent lucidophyllous forest at Taisanji Temple, Hyogo Prefecture, Japan (34°41'N, 135°04'E, 70–200 m ASL, Fig. 1). The substrate of the slopes surrounding Taisanji Temple is granite (Kodate and Nakanishi 1986). Historical drawings from 1803 suggest that the surrounding vegetation was open pine forest (Matsushita 1997). Vegetation maps and survey data from 1960-1970 indicate evergreen forests had established surrounding the temple grounds suggesting succession had proceeded (Kodate and Nakanishi 1986). The evergreen

95 forest, directly behind the temple grounds, is a place of Buddhist training and has had minimal human  
96 intervention. The mature lucidophyllous forest is dominated by *Castanopsis cuspidata* and comprises  
97 many indigenous species, representative of climax forest in this region (Ishida et al. 1998). Adjacent  
98 to the mature lucidophyllous forest is unmanaged secondary forest (abandoned satoyama), where  
99 neighboring farmers had actively utilized the forest until ca. 1960s. The secondary forest is dominated  
100 by deciduous broad-leaved trees. Observations suggest, after management ceased, evergreen trees  
101 from the lucidophyllous forest are slowly invading into the secondary forest creating a spatial gradient  
102 of forest succession with increasing distance from the lucidophyllous forest.

103 We established two permanent plots to observe vegetation dynamics. The mature  
104 lucidophyllous forest (M) plot (50x50 m) was established in 2003 at the foot of the hill on the temple  
105 side, while the far-secondary forest (F) plot (50x40 m) was established in 2005 in the unmanaged  
106 secondary forest on the opposite side of the hill (Fig 1). These plots are the same as those studied by  
107 Azuma et al. (2014). We counted approximately 100 annual rings in a core sample taken at 30 cm  
108 height from the trunk of the largest tree in the M plot in 2012 (*C. cuspidata*, DBH=78 cm), suggesting  
109 the forest is near climax stage. In the F plot, we counted 60-70 annual rings from core samples from  
110 the stems of multi-stemmed *Quercus serrata* and *Quercus variabilis* trees, suggesting the secondary  
111 forest was last cut around 1950 (Azuma et al. 2014). We measured diameter at breast height (DBH,  
112 1.3 m above ground) and height of all trees taller than 1.3 m within the research plots using diameter  
113 tapes, digital calipers (for DBH < 2 cm), telescoping poles (height < 8 m), and ultra-sound clinometers

114 (Vertex III, Haglof, Sweden). Diameter measurements were repeated in 2008, 2014 and 2020. Height  
115 measurements were repeated in 2014 and 2020. These two plots were used to observe temporal change  
116 in species composition and stand structure.

117 In 2020, we established two additional research plots [near the ridge of the hill](#) between the [M](#)  
118 and F plots to investigate spatial variation of species composition and stand structure with increasing  
119 distance from the mature lucidophyllous forest. The young lucidophyllous forest ([Y](#)) plot (20x30 m)  
120 is located in a relatively young lucidophyllous forest ca. 100 m [upslope](#) from the [M](#) plot ([Fig. 1](#)). The  
121 close-secondary (C) forest plot (20x40 m) is located in a mixed evergreen-deciduous forest on the  
122 mature forest side, [upslope](#) of the F plot. Plot sizes are variable reflecting the spatial extent of each  
123 forest type. We counted 48-65 annual rings in core samples taken at 30 cm height from trunk of the  
124 largest trees in the [Y](#) and C plots (all *C. cuspidata*), indicating that the [Y](#) plot is younger than the [M](#)  
125 plot and that the oldest *C. cuspidata* trees established in the C plot soon after management ceased.  
126 DBH and tree height of all trees taller than 1.3 m in [Y](#) and C plots were measured using the same  
127 criteria and methods as for the [M](#) and F plots above.

128

#### 129 *Data analysis*

130 Using the DBH data in each survey year, we calculated basal area (BA, m<sup>2</sup> ha<sup>-1</sup>) for each tree species  
131 in the plots. We used the Chao-Jaccard index to compare species composition among the plots based  
132 on abundance (trees ha<sup>-1</sup>) and the Bray-Curtis index to compare stand structure based on BA. We chose

133 Chao-Jaccard over the Bray-Curtis index for abundance because the Bray-Curtis index is heavily  
134 influenced by the relative abundance of species. The Bray-Curtis index can be calculated based on  
135 relative abundance of species (e.g., De Caceres et al. 2013; Hao et al, 2019), indicating that the  
136 independent variables need not be count data. Several previous studies have applied the Bray-Curtis  
137 index to assess similarity in stand structure among communities using relative basal area (e.g., La  
138 Torre-Cuadros et al, 2007; Hotta et al, 2015; Sasaki et al. 2018).

139 The results were visualized using non-metric multidimensional scaling (nMDS) ordination  
140 using the function “metaMDS” of the package “vegan” in R software (ver. 3.4.1, R Development Core  
141 Team) (Oksanen et al. 2020). The nMDS is a distance-based ordination technique where relationships  
142 among biological communities are drawn on a two-dimensional plane to display graphically  
143 similarities among ecological communities. It is suited for ecological analyses because it is  
144 nonparametric and can be used to relativize distance measures based on a wide variety of ecological  
145 data (McCune et al. 2002). Distance between plots on the nMDS ordination plane represent their  
146 relative similarities. Here, changes over time of the coordinates of the F plot relative to the M plot on  
147 the nMDS ordination plane was interpreted as the course of succession (Hiers et al. 2012; Mathews et  
148 al. 2010; Ruiz-Jaen and Aide 2006). We used type-two permutational multivariate analysis of variance  
149 (PERMANOVA) using distance matrices and evaluated plot distances on the nMDS plane to test  
150 significant change over time and differences among plots in species composition and stand structure,  
151 respectively. PERMANOVA (9999 permutations) was conducted using the function “adonis2” of the

“vegan” package in R. Multiple comparisons for evaluating distances between plots were conducted using the “pairwiseAdonis2” package, where p-values of the pairwise PERMANOVA are corrected using the Holm correction (Hervé 2016). In addition to visualizing similarity among communities, correlations between the original species vectors, abundance/dominance of a species in each community, and the axis scores of the nMDS ordination can be computed and these correlations scaled to represent the direction and strength of influence of species on each community (Legendre and Gallagher 2001). To infer species that affected composition and structure of the study plots, we plotted species having significant correlations with axes 1 and 2 on the nMDS ordination plane.

160

## 161 **Results**

### 162 *Temporal change of species composition and stand structure*

163 Comparison of DBH distributions between 2003 and 2014 indicated that species composition and size  
164 distribution of the M plot had changed very little between surveys and was characterized by dominance  
165 of shade-tolerant, climax species, such as *C. cuspidata*, *Aucuba japonica*, *Camellia japonica* and  
166 *Cleyera japonica* (Fig. 2). In contrast, species composition of the F plot in 2005 was characterized by  
167 dominance of shade-intolerant, deciduous (e.g., *Q. serrata*, *Lyonia ovalifolia*) and evergreen (e.g., *Ilex*  
168 *pendiculosa*, *Quercus phillyraeoides*) trees and deciduous shrubs (e.g., *Rhododendron reticulatum*).  
169 While stem density remained relatively stable in both plots (ca. 2400 and 3800 trees ha<sup>-1</sup>, for M and F  
170 plots, respectively, Table S1, S2), total BA increased by 22% (from 37.11 m<sup>2</sup> ha<sup>-1</sup> in 2003 to 45.27 in

171 2020) in the M plot and by 37% (21.66 m<sup>2</sup> ha<sup>-1</sup> in 2003 to 29.67 in 2020) in the F plot (Table S3, S4).

172 Comparison of height distributions between 2003 and 2014 indicated that canopy height of  
173 the M plot increased, but the relative vertical distribution of species remained stable (Fig. 2). The upper  
174 canopy continued to be dominated by *C. cuspidata*, which had the largest BA (Table S3), and the lower  
175 canopy by *Camellia japonica*. Canopy height of the F plot also increased. While *Q. serrata* continued  
176 to dominate in the upper-canopy as well as in BA (Table S4), marked changes were observed in the  
177 vertical distribution of species in the mid- and lower-canopy layers. *Q. phillyraeoides* and *Ilex*  
178 *pedunculosa* increased markedly in height and BA and dominated the mid-canopy in 2014, while in  
179 the lower canopy, deciduous species (e.g., *R. reticulatum*, *L. ovafolia*) decreased and evergreen species  
180 (e.g., *Camellia japonica*, *Cleyera japonica*) increased.

181 Abundances of the dominant climax species in the M plot were positively correlated with  
182 Axis 1 and negatively correlated with Axis 2 of the abundance-based nMDS ordination plane, while it  
183 was vice versa for the dominant species of the F plot (Fig. 3). The BA of *C. cuspidata* was positively  
184 correlated, while that of the dominant species in the F plot was negatively correlated with Axis 1 of  
185 the BA-based nMDS ordination plane. During the study period, the coordinates of the M plot changed  
186 very little in relation to Axis 1 of both the abundance- and BA-based nMDS, reflecting stable species  
187 composition and stand structure. In contrast, Axis 1 values of the F plot tended to increase toward the  
188 direction of the M plot, although these changes were not statistically significant (Table 1, 2).

189

## *Spatial variation with distance from mature forest*

Results of the most recent survey in 2020 indicated that the **M** and **Y** plots were dominated by *C. cuspidata* with *Camellia japonica* and other evergreen species comprising the mid- to lower-canopy layers (**Fig. 4**). The DBH and height of *C. cuspidata* in the **Y** plot were smaller than in the **M** plot, reflecting the difference in stand age. Compared to the F plot, where the upper-canopy and BA were both dominated by *Q. serrata*, *C. cuspidata* dominated the upper-canopy of the C plot and evergreen species contributed larger proportion of the total BA (**Table S6**). The mid-canopy layer was more developed in the C plot, where *I. pedunculosa*, *Q. phillyraeoides* and *Clethra barbinervis* dominated in the mid-DBH (10-20 cm) and mid-height (7.3-13.3 m) classes. Shade-intolerant deciduous species (*R. reticulatum*, *L. ovalifolia*) were less abundant in the lower-canopy layer of the C plot.

Abundance-based nMDS indicated that species compositions of the **M** and **Y** plots were very similar to each other (**Fig. 5, Table 3**). Species composition of the F and C plots were different from the **M** and **Y** plots, as well as from each other. BA-based nMDS indicated that, stand structure of the **M** and **Y** plots differed from each other, reflecting the difference in size distribution of the dominant species (**Table 4**). Stand structure of the F and C plots differed from **M** and **Y** plots, as well as from each other, reflecting the difference in vertical distribution of species.

## **Discussion**

Our results indicated that, in contrast to the dynamic changes observed in the far-secondary forest

209 during the study period, species composition and stand structure of the **mature** lucidophyllous forest  
210 remained relatively stable, suggesting it is approaching climax state. In the far-secondary forest, shade-  
211 intolerant species, such as *R. reticulatum* and *L. ovalifolia*, decreased markedly in the lower-canopy  
212 layer during the study period and were replaced by shade-tolerant evergreen species. Similar vegetation  
213 dynamics have been observed in unmanaged secondary forests in many regions in Japan (Nakajima et  
214 al. 2018). For example, in an unmanaged, secondary broad-leaved forest in Kyoto, tree density  
215 decreased over a 12-year period as shade-intolerant shrubs were replaced by evergreen species such as  
216 *Cleyera japonica* and *E. japonica*, whereas total basal area increased due to growth of the canopy  
217 dominant trees (Ito 2007). Hirayama et al. (2011) compared species composition between mid-  
218 successional forest dominated by *Q. serrata* and *Q. variabilis* (abandoned satoyama), with that of a  
219 late-successional forest dominated by *C. cuspidata*, and found that the former had a more developed  
220 shrub layer. Morimoto and Yoshida (2005) found that between 1974 and 1995, native *Rhododendron*  
221 populations in Kyoto city had declined as the number of unmanaged secondary forests increased.  
222 Traditional coppice management maintained the forests at early stages of succession with open canopy  
223 conditions (Kobori and Primack 2003). Our results together with reports from other unmanaged  
224 satoyama across Japan suggest that, after management ceased, growth and increasing leaf area of the  
225 upper-canopy trees reduce the amount of light penetrating into the forest such that, in the lower-canopy,  
226 shade-intolerant species gradually decline and are replaced by shade-tolerant evergreen species.

227 In warm-temperate Japan, the dominant canopy species are expected to succeed from shade-

228 intolerant, deciduous oaks to shade-tolerant, evergreen oaks (Miyawaki 2004). Seeds of these  
229 Fagaceous species (acorns) are mostly gravity and animal dispersed. In secondary forests in Japan,  
230 acorns may be transported 20 m to as much as 40 m by rodents (Iida 1996). Birds can also transport *C.*  
231 *cuspidata* acorns over long distances (Hiroki 2001). In a secondary forest dominated by *Q. variabilis*  
232 and *Q. serrata*, continuous recruitment and gradual invasion of *C. cuspidata* into the secondary forest  
233 occurred, such that seedlings of *C. cuspidata* established as far as 40 m away from the nearest adult  
234 trees in the adjacent *C. cuspidata*-dominated forest (Hirayama et al. 2010). Our results indicated  
235 evergreen trees and shrubs, originating from the lucidophyllous forest are invading the lower-canopy  
236 of the secondary forest. The direction of temporal change on the nMDS ordination plane suggested  
237 that the secondary forest is succeeding toward the climax, lucidophyllous forest following the normal  
238 sere for warm-temperate Japan. The marked difference in canopy structure between the mature and  
239 secondary forests, however, indicated seedlings and young trees of *C. cuspidata* in the lower canopy  
240 of the secondary forest are far from attaining dominant status, because deciduous oaks and shade-  
241 intolerant evergreen trees continue to dominate the upper canopy. Slope position may also affect stand  
242 growth and management history. Growth of *C. cuspidata* may be slower in the upper-slope stands (Y  
243 and C plots). Because of its lower-slope position (i.e., ease of access), the F plot may have been  
244 managed more frequently than the C plot, maintaining the far-secondary forest at early-successional  
245 stage until more recently.

246

## 247 **Conclusions**

248 Spatio-temporal analysis of species composition and stand structure of unmanaged, secondary forest  
249 adjacent to [mature](#) lucidophyllous forest using nMDS ordination allowed us to infer the course of  
250 succession of unmanaged satoyama. Past management practices, such as coppice forestry in the case  
251 of satoyama, may continue to influence composition and structure of ecosystems for decades to  
252 centuries (Bürgi et al. 2013; Douda et al. 2017; Perring et al. 2016). In addition, connectivity, seed flux,  
253 and colonization among different communities within a landscape influence species composition  
254 (Martín-Queller and Saura 2013). The lack of source populations in human-dominated landscapes can  
255 cause recruitment limitation arresting vegetation dynamics at mid-succession (Acácio et al. 2007;  
256 Duelli and Obrist 2003). Remnants of natural and semi-natural habitats can function as refugia for rare  
257 species and as stepping stones for species dispersal, contributing to restoration of inherent vegetation  
258 dynamics at the landscape level (Duelli and Obrist 2003). Although dynamic changes in species  
259 composition, especially in the lower-canopy, have been observed in many unmanaged satoyama, our  
260 results suggested [legacy effects](#) of satoyama management can persist for several decades before  
261 individual canopy trees are replaced by natural disturbances such as typhoon, and the unmanaged  
262 secondary forest attains climax composition and structure. In this study, the adjacent lucidophyllous  
263 forest acted as a seed source for recruitment of shade-tolerant species into the unmanaged, secondary  
264 forest. However, for secondary forests which lack nearby seed sources of climax species, close  
265 monitoring of vegetation change may be necessary to prevent arrested or diverted succession. Further

266 studies should elucidate dynamics of unmanaged satoyama in the context of landscape-level  
267 distribution of natural and semi-natural forests.

268

## 269 **Acknowledgements**

270 We thank Taisanji Temple for allowing us to conduct field work on their sacred mountain. We also  
271 thank members of the Laboratory of Forest Resources, Kobe University for field assistance, especially  
272 A. Iwasaki, Y. Ohsugi, and S. Doi, who led past field surveys. We thank Dr. H. Rockwell for thoroughly  
273 checking the English.

274

## 275 **Author contributions**

276 HI conceived and designed the study. Fieldwork and data collection was led by NK with assistance  
277 from TY, KH, and WAA. TY and NK analyzed the data together and prepared all figures. HI wrote the  
278 first draft of the manuscript. All authors have approved the final manuscript.

279

426 **Figure captions**

427 Fig. 1. Location of the study site, Taisanji Temple, in Kobe City, Japan (a). The mature lucidophyllous  
428 forest is located on the west side of the mountain (b, solid outline). The east side of the ridge-  
429 line is secondary forest, which was cut regularly to obtain fire-wood until ca. 60 years ago, after  
430 which it was abandoned (b, dotted outline). Climax species originating from the lucidophyllous  
431 forest are invading into the secondary forest. Four study plots were established along the spatial  
432 gradient of vegetation change with increasing distance from the mature lucidophyllous forest:  
433 mature lucidophyllous (M), young lucidophyllous (Y), close-secondary (C), and far secondary (F)  
434 plots.

435 Fig. 2. Temporal change of diameter and height distributions of species in the mature lucidophyllous and  
436 far-secondary forest plots during the study period. The bars for the smallest diameter/height  
437 classes in each plot are truncated and numbers next to the bars indicate number of trees.

438 Fig. 3. Nonmetric multidimensional scaling (nMDS) ordination of vegetation similarity based on  
439 abundance and basal area of the mature lucidophyllous (M, □) and the far secondary (F, ○) plots  
440 during the study period. Coordinates of each species (+: deciduous, X: evergreen) reflect  
441 correlations with each nMDS axis. Stress values are < 0.01 for both abundance and basal area.

442 Fig. 4. Diameter and height distributions of species in the four research plots in 2020. The bars for the  
443 smallest diameter/height classes in each plot are truncated and numbers next to the bars indicate  
444 number of trees.

445 Fig. 5. Nonmetric multidimensional scaling (nMDS) ordination of vegetation similarity based on  
446 abundance and basal area of the mature lucidophyllous (M, □), young lucidophyllous (Y, ◇), far  
447 secondary (F, ○) and close-secondary (C, Δ) plots in 2020. Coordinates of each species (+:  
448 deciduous, X: evergreen) reflect correlations with each nMDS axis. Stress values are less than  
449 0.01 for both abundance and basal area.

Table S5. Species composition and stand structure of the young lucidophyllous forest (Y) plot in 2020.

Species are listed in order of decreasing basal area. Bold letters indicate evergreen species.

Young lucidophyllous Species	2020	
	Abundance (ha <sup>-1</sup> )	BA (m <sup>2</sup> ha <sup>-1</sup> )
<i>Castanopsis cuspidata</i>	483	28.77
<i>Quercus myrsinifolia</i>	100	4.36
