Abstract

In our previous study, we detected a QTL for the oleic acid percentage (C18:1) on BTA9 in Japanese Black cattle through a genome-wide association study (GWAS). In this study, we performed whole-genome resequencing on eight animals with higher and lower C18:1 to identify candidate polymorphisms for the QTL. A total of 39,658 polymorphisms were detected in the candidate region, which were narrowed to 1,993 polymorphisms within 23 genes based on allele differences between the high and low C18:1 groups. We subsequently selected three candidate genes, i.e., *CYB5R4*, *MED23*, and *VNN1*, among the 23 genes based on their function in fatty acid metabolism. In each candidate gene, three SNPs, i.e., *CYB5R4* c.*349G>T, *MED23* c.3700G>A, and *VNN1* c.197C>T, were selected as candidate SNPs to verify their effect on C18:1 in a Japanese Black cattle population (n = 889). The statistical analysis showed that these SNPs were significantly associated with C18:1 ($p < 0.05$), suggesting that they were candidates for the QTL. In conclusion, we successfully narrowed the candidates for the QTL by detecting possible polymorphisms located within the candidate region. It is expected that the responsible polymorphism can be identified by demonstrating their effect on the gene's function.

Keywords: *fatty acid composition, Japanese Black cattle, oleic acid percentage, whole-genome resequencing*

Introduction

In our previous study, we identified a QTL for the oleic acid percentage (C18:1) on BTA9 when a genome-wide association study (GWAS) was conducted on a Japanese Black cattle population (Kawaguchi et al. 2018). We searched for genes involved in fatty acid metabolism using the NCBI database to identify candidate genes around the QTL. We ultimately selected *VNN1* as a candidate gene because it was involved in fatty acid synthesis. A putative candidate SNP, c.197C>T (T66M), was detected within the gene. To verify the effect of this SNP on C18:1, we investigated the association between this SNP and C18:1 in a Japanese Black cattle population. Although the SNP was significantly associated with C18:1, its *p*-value was higher than that of the most significant SNP identified during the GWAS. Therefore, we concluded that another polymorphism might be responsible for the QTL.

Whole-genome resequencing has recently been used for detecting polymorphisms that might affect the economic traits of livestock animals. Jiang et al. (2016) used whole-genome resequencing to detect short indels in eight dairy cattle with high and low estimated breeding values (EBV) for their milk composition traits. They compared genotypes in eight animals to select candidate

indels. Since the responsible indel would show different genotype between high EBV and low EBV animals, they selected indels showing almost the same genotype in four animals in each group and showing the different alleles between high and low animals. To select candidate genes from several genes containing the candidate indels, they collected some information on the pathways, QTL registered on databases, and positions of the significant SNPs identified by GWAS in previous reports. They ultimately identified 11 candidate genes based on functional and positional information. Li et al. (2015) also used whole-genome resequencing in 10 birds to detect SNPs for pH value of chicken meat in a fine-mapped QTL on chromosome 1. Half of the birds were homozygous for the high-QTL allele (QQ group), and the remaining birds were homozygous for the low QTL allele (qq group). They extracted SNPs that exhibited different alleles between the high and low QTL groups and focused on the SNPs expected to affect the gene's function, according to their annotations (such as non-synonymous, UTR, splicing sites, CpG island, and promoter regions). They conclusively identified 129 SNPs as candidates for the QTL.

Previous studies suggest that whole-genome resequencing is a useful method for identifying candidate polymorphisms and genes. The objective of this

study was to identify candidate polymorphisms and genes for the QTL for C18:1 on BTA9 using whole-genome resequencing.

Materials and Methods

Sample selection

In our previous study, we used Japanese Black cattle population comprising 1836 animals that had been bred in the Hyogo Prefecture (Kawaguchi et al. 2018). After correcting for the C18:1 phenotype of each animal using an analytical model, we selected a total of 200 animals for conducting pool-based GWAS: 100 of these animals had higher C18:1 and the other 100 had lower C18:1 in the previous study.

In this study, eight animals were selected from the 200 animals used in the GWAS for whole-genome resequencing based on their sires and genotype of the most significant SNP in the GWAS (Hapmap43702-BTA-84086) (Table 1). We selected four animals with the TT genotype from the 100 “high” animals and four animals with the CC genotype from the 100 “low” animals, which were the progenies of different sires among the four animals in the high and low groups. Genomic DNA was extracted from each 50-mg longissimus cervicis muscle

sample following the standard phenol-chloroform method.

Whole-genome resequencing

DNA degradation was monitored based on its concentration by spectrometry, fluorometry, and 1% agarose gel electrophoresis. A paired-end library was constructed using high-quality DNA for each individual, and its read length was 150 bp. Sequencing was performed using a HiSeq X Five Sequencing System (Illumina Inc., San Diego, CA, USA). Sequencing data were normalized by Genedata Expressionist 9.1.4a. We mapped the reads to the cattle reference genome assembly (UCSC bosTau8) downloaded from the UCSC Genome Browser assembly (https://genome-asia.ucsc.edu/cgi-bin/hgGateway) using BWA-MEM 0.7.12. and excluded PCR duplicates using Picard 2.2.4. GATK 3.6 (2016-12-08-g1c2527f) was used to call polymorphisms by comparing the genome sequences, including the reference sequence. The polymorphisms were annotated to the gene reference (NCBI RefSeq) based on their location (intron, exon, untranslated region, upstream, downstream, splice site, and intergenic region) and characteristics (synonymous/non-synonymous amino acid replacement, gain/loss of start/stop site, and frameshift mutations) using SnpEff

v4.2 with the reference sequence (bosTau8).

Narrowing the polymorphisms and genes

In our previous study, we determined the region 5 Mbp upstream and downstream of Hapmap43702-BTA-84086 (64.9 –74.9 Mbp) to be the candidate region (Kawaguchi et al. 2018). In this study, we selected polymorphisms in the candidate region from among all the polymorphisms detected by whole-genome resequencing.

We first excluded intergenic polymorphisms and subsequently focused on the linkage disequilibrium (LD) between the polymorphisms and Hapmap43702-BTA-84086 because the responsible polymorphism is in LD with Hapmap43702-BTA-84086. We compared genotypes of four animals in high group with those of four animals in low group as an indicator of LD. The Hapmap43702-BTA-84086 genotypes completely differed between the high and low groups; it was defined that there were a total of eight allele differences between the high and low groups. Therefore, polymorphisms with a large number of allele differences were expected to be in LD with the SNP. In this study, we focused on the polymorphisms with over three allele differences.

We investigated the function of genes containing these polymorphisms in the NCBI database and previous reports and determined candidate genes based on their function in fatty acid metabolism, such as synthesis, transport, desaturation, and oxidation.

Genotyping the candidate SNPs

Polymorphisms were prioritized as candidates based on their location and characteristics. We selected candidate polymorphisms that were the most likely to affect the function of each candidate gene.

To test the effect of candidate polymorphisms on C18:1, we used a Japanese Black cattle population (n = 899) that had been randomly selected from 1836 individuals bred in the Hyogo Prefecture, Japan, and graded them from 2010 to 2012. This population contained at least 10 offspring per each sire. We genotyped *CYB5R4* c.*349G>T and *MED23* c.3700G>A by PCR-RFLP. The primer sets for PCR amplification were designed based on the GenBank sequence (AC_000166.1) using OLIGO 7.41. The PCR reaction was performed at the annealing temperature and extension period shown in Table 2. The PCR products for *CYB5R4* c.*349G>T and *MED23* c.3700G>A were digested using

*Msl*I and *Sca*I, respectively.

Statistical analysis

We performed statistical analysis using the same samples and methods described in our previous study (Kawaguchi et al. 2018). To correct the phenotype, a linear mixed model was applied to C18:1 as follows:

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_1\mathbf{u}_1 + \mathbf{Z}_2\mathbf{u}_2 + \mathbf{e}$$

where **y** is a vector of observations (C18:1); **b** is a vector of fixed effects including overall mean, slaughter year, slaughter month, sex of animals, linear covariate for inbreeding coefficient, and linear and quadratic covariates for age at slaughter; $\mathbf{u}_1$ and $\mathbf{u}_2$ are vectors of random farm and animal genetic effects, respectively; **e** is a vector of random residual effects; and **X**, $\mathbf{Z}_1$, and $\mathbf{Z}_2$ are known incident matrices. Restricted maximum likelihood by the expectation-maximization algorithm (EM-REML) and best linear unbiased prediction (BLUP) were employed to estimate variance components and all random effects in the model, respectively. A total of 8661 animals including ancestors were evaluated and the heritability was estimated to be 0.423 ± 0.119.

The e-values of 899 animals were analyzed by one-way analysis of variance

(ANOVA) with genotype as a source of variation and Tukey-Kramer's honestly significant difference (HSD) test implemented in JMP13 (SAS institute Inc., Cary, NC, USA).

The proportion of additive genetic variance was calculated following the method of Matsuhashi et al. (2011). LD coefficients (r^2) between the polymorphisms were calculated using HAPLOVIEW 4.0.

Results

Detection of candidate polymorphisms by genome resequencing

We conducted whole-genome resequencing in eight Japanese Black cattle (Table S1). A total of 39,658 polymorphisms were identified in the candidate region (Chr 9: 64,956,436–74,956,436) by comparing genome sequences between nine animals, including the reference (bosTau8). Of these, 10,045 polymorphisms were located within the genes. We further narrowed the polymorphisms to 1,993 with over three allele differences between the high and low groups, which were located within a total of 23 genes. These SNPs were counted based on genes and annotations to select the candidate polymorphisms (Table S2).

Candidate genes in terms of gene function

We investigated the functions of the 23 genes based on information in the NCBI database and previous reports (Table S3). Three genes, i.e., *CYB5R4*, *MED23*, and *VNN1*, were determined to be candidate genes in terms of their function in fatty acid metabolism.

CYB5R4 is an electron donor for fatty acid desaturation by stearoyl-CoA desaturase (SCD) (Zhu et al. 2004; Deng et al. 2010). Larade et al. (2008) reported that the C18 desaturation index (C18:1/C18:0) was markedly lower in *CYB5R4*-knockout mouse than in a wild-type mouse. Polymorphisms within the *CYB5R4* gene may affect SCD activity, which would alter the ratio between C18:1 and C18:0.

MED23 is a subunit of the Mediator complex and transmits information between RNA polymerase II and transcription factors, such as FOXO1 (Knuesel and Taatjes 2011; Chu et al. 2014). A previous study reported that FOXO1 suppresses the expression of acetyl-CoA carboxylase (ACC), which catalyzes the carboxylation of acetyl-CoA to malonyl-CoA, i.e., the first step of long-chain fatty acid synthesis (Bastie et al. 2005). MED23 may control fatty acid synthesis by

regulating the expression of ACC.

VNN1 is an enzyme that controls the amount of pantethine generate by pantetheinase activity (Pitari et al. 2000; Kavian et al. 2015). Acetyl-CoA and malonyl-CoA are converted to acetyl-ACP and malonyl-ACP, respectively, during one step of fatty acid synthesis. As pantethine bypasses this reaction as a metabolically active substrate for CoA and ACP (Kelly 1997), VNN1 appears to be involved in fatty acid synthesis.

The effect of the candidate SNPs on C18:1

A total of 77, 125, and 28 polymorphisms were detected within the *CYB5R4*, *MED23*, and *VNN1* genes, respectively (Table S2). We selected one candidate polymorphism from each candidate gene to test its effect on C18:1. We primarily focused on amino acid substitutions and secondarily focused on SNPs related to gene expression (5′UTR, 3′UTR, the promoter region, and splice site). The amino acid substitutions, V1234I and T66M, were selected within *MED23* and *VNN1* genes, respectively, while we selected the SNP on 3'UTR in *CYB5R4* gene since amino acid substitution was not detected within the gene (Table S2). In short, *CYB5R4* c.*349G>T, *MED23* c.3700G>A (V1234I), and *VNN1* c.197C>T (T66M)

were selected as candidate SNPs for the QTL. *VNN1* c.197C>T was selected as a candidate SNP in our previous study (Kawaguchi et al. 2018).

We previously genotyped the most significant SNP in GWAS (Hapmap43702-BTA-84086) and *VNN1* c.197C>T for a Japanese Black cattle population (n = 899) (Kawaguchi et al. 2018). In addition, we genotyped *CYB5R4* c.*349G>T and *MED23* c.3700G>A for the same population in the current study. The minor allele frequencies of Hapmap43702-BTA-84086, *CYB5R4* c.*349G>T, *MED23* c.3700G>A, and *VNN1* c.197C>T were 0.261, 0.272, 0.280, and 0.201, respectively (Table 3). These SNPs were in relatively high LD with Hapmap43702-BTA-84086 (r^2 = 0.53–0.83) (Fig. 1). In our previous study, statistical analysis revealed that Hapmap43702-BTA-84086 and *VNN1* c.197C>T were significantly associated with C18:1 (p = 0.0080 and 0.0162, respectively) (Kawaguchi et al. 2018). Therefore, we also conducted statistical analysis for *CYB5R4* c.*349G>T and *MED23* c.3700G>A to investigate and compare their effects on C18:1. ANOVA revealed that both SNPs were significantly associated with C18:1 (p = 0.0075 and 0.0295) (Table 4). Significant differences between genotypes were observed by the Tukey–Kramer's HSD test. The proportions of additive genetic variance for Hapmap43702-BTA-84086, *CYB5R4* c.*349G>T,

MED23 c.3700G>A, and *VNN1* c.197C>T were 3.70, 4.20, 3.30, and 2.24, respectively.

Discussion

We focused on three genes, i.e., *CYB5R4*, *MED23*, and *VNN1*, as candidates for the QTL based on whole-genome resequencing data and functional information. For each gene, we selected *CYB5R4* c.*349G>T, *MED23* c.3700G>A, and *VNN1* c.197C>T as candidate SNPs. One of them, *VNN1* c.197C>T, has been selected as the candidate SNP and genotyped in a Japanese Black cattle population (n = 899) in our previous study (Kawaguchi et al. 2018). We additionally genotyped the other two SNPs in the same Japanese Black cattle population and then calculated the LD coefficient between the SNPs and Hapmap43702-BTA-84086. Previous studies reported that the average LD coefficient (r^2) between markers was < 0.1 in Japanese Black cattle, even at a distance of 2 Mbp (McKay et al. 2007), and the LD block size ranges were 0.022 – 2.5 Mbp in three chromosomes in Japanese Black cattle (Watanabe et al. 2008). However, the population in our study was expected to have a wider LD block as they undergo uniquely closed breeding (Nakajima et al. 2018). In this study,

CYB5R4 c.*349G>T exhibited a high LD coefficient with Hapmap43702-BTA-84086 (r^2 = 0.77) despite its location at approximately 4 Mbp away from the SNP. This result is consistent with the expectation of a longer average distance between polymorphisms in LD of the population compared with that in other Japanese Black cattle populations. In addition, all three candidate SNPs were in relatively high LD, suggesting that the number of allele differences is an appropriate indicator of LD with Hapmap43702-BTA-84086.

In this study, we compared the effect of three candidate SNPs on C18:1 in the Japanese Black cattle population. Although three SNPs were significantly associated with C18:1, only *CYB5R4* c.*349G>T exhibited a smaller *p*-value than that Hapmap43702-BTA-84086. In addition, this SNP exhibited the highest additive genetic variance among the four SNPs, including Hapmap43702-BTA-84086. These results suggest that *CYB5R4* c.*349G>T is the most likely candidate for the QTL among the three candidate SNPs, which were located on *CYB5R4* 3′UTR, and may, therefore, affect gene expression. CYB5R4 is an essential electron donor for Δ9 fatty acid desaturation by SCD (Holloway & Katz 1972; Larade et al. 2008; Zhu et al. 1999), and the SNP may be responsible for C18:1 through the alteration of SCD activity based on the *CYB5R4* gene

expression level.

Although their *p*-values were larger than that of *CYB5R4* c.*349G>T, the other two SNPs exhibited a similar *p*-value to that of Hapmap43702-BTA-84086, suggesting that they could also be candidates for the QTL. While we successfully narrowed the candidate polymorphisms and genes based on whole-genome resequencing data and functional information, it was not possible to determine the responsible polymorphism for the QTL in this study. Therefore, we must verify possibilities for all polymorphisms, including *CYB5R4* c.*349G>T, *MED23* c.3700G>A, and *VNN1* c.197C>T, to be the responsible polymorphism. In addition, we must demonstrate the effect of the candidate polymorphisms on the gene's functioning to identify which is responsible. In conclusion, we obtained beneficial information to prioritize candidates in this study. We will identify the responsible polymorphism by conducting further analysis.

The results of Hapmap43702-BTA-84086 and *VNN1* c.197C>T were cited from Kawaguchi *et al.* (2018)

TABLE 4 Effect of Hapmap43702-BTA-84086 and the three candidate SNPs on C18:1 in the Japanese Black population (n = 899)

Polymorphism	e-values ± SE			*p*-value	%VA
Hapmap43702-BTA-84086	TT	TC	CC		
	0.032 [a] ± 0.085	-0.234 [ab] ± 0.095	-0.736 [b] ± 0.273	0.0080	3.70
CYB5R4 c.*349G>T	GG	GT	TT		
	0.056 [a] ± 0.087	-0.261 [b] ± 0.093	-0.636 [b] ± 0.279	0.0075	4.20
MED23 c.3700G>A	AA	AG	GG		
	0.018 ± 0.088	-0.205 ± 0.091	-0.652 ± 0.274	0.0295	3.30
VNN1 c.197C>T	CC	CT	TT		
	-0.050 [a] ± 0.078	-0.158 [a] ± 0.106	-1.054 [b] ± 0.344	0.0162	2.24

The results of Hapmap43702-BTA-84086 and *VNN1* c.197C>T were cited from Kawaguchi *et al.* (2018)

e-values: the mean of e-values for C18:1 for each genotype

%VA: the proportion of additive genetic variance

a, b: means with different superscript are significantly different between genotypes
